Abstract

A liquid Argon TPC (ICARUS-like) has the ability to detect neutrino bursts from type-II supernova collapses, via three processes: elastic scattering by electrons from all neutrino species, and ν_e charged current absorption on Ar with production of excited K and $\bar{\nu}_e$ charged current absorption on Ar with production of excited Cl . In this paper we have used new calculations in the random phase approximation (RPA) for the absorption processes. The anti-neutrino reaction $\bar{\nu}_e$ ^{40}Ar absorption has been considered for the first time. For definiteness, we compute rates for the 3 kton ICARUS detector: 244 events are expected from a supernova at a distance of 10 kpc, without considering oscillation effects. The impact of oscillations in the neutrino rates will be discussed in a separate paper. We also discuss the ability to determine the direction of the supernova.

1 Introduction

When a massive star (eight or more times the mass of the Sun) runs out of nuclear fuel, it develops a layered structure, which heavier elements lay in deeper layers, the innermost element being iron. This configuration becomes eventually unstable and leads to a catastrophic collapse of the star core in a time window of a few thousandths of a second, since the star cannot resist the pressure of its internal gravitational force. This collapse leads to an explosion that is known as type II supernova [1]. The expected rate for such an event to occur in our Galaxy is one every thirty years [2].

The binding energy released during this process is enormous: 10^{53} ergs. The high density prevents the emission of photons, therefore 99% of the energy comes out in the form of neutrinos of all types. A small fraction of them, about 1%, are produced during the neutronization process through the reaction $e^- + p \rightarrow \nu_e + n$, while the rest are $\nu\bar{\nu}$ pairs from later cooling reactions.

On their way out, neutrinos interact inside the stellar core which is an extremely dense and neutron-rich medium. The different scattering reactions, underwent by every neutrino species, result in different energy distributions for the emitted neutrinos. Muon and tau neutrinos interact only through weak neutral currents, thus they decouple deep inside the core, where a higher temperature exists, and therefore are emitted with higher energies compared to ν_e 's and $\bar{\nu}_e$'s. In addition, $\bar{\nu}_e$'s suffer fewer charged current interactions than ν_e 's, so they decouple in hotter regions, thus having an energy spectrum that is harder than that of ν_e 's.

The neutrino signal from a supernova rises first steeply and then falls exponentially with time (see [3]). The experimental detection of a neutrino signal from a supernova is therefore expected to occur in a time window of about 10 seconds. This implies that detector thresholds can, in principle, be set quite low since backgrounds are highly suppressed given the narrow time window in which the burst takes place.

The detection of neutrinos emitted by SN1987A in Kamiokande [4] and IMB [5] began the era of neutrino astronomy. Nowadays, several running or planned experiments (SuperKamiokande, SNO, LVD, KamLAND, Borexino...) have the capability to unambiguously detect supernova neutrinos [6, 7].

As discussed in [1, 8], a liquid Argon TPC like in ICARUS has the ability to detect neutrino bursts from supernova collapses. Preliminary estimates of the expected rates yielded 76 events (44 from ν_e absorption and 32 from electron scattering assuming a 5 MeV electron detection threshold)[8] for a supernova at 10 kpc. For the absorption cross section, a threshold of 11 MeV was taken into account¹. The energy threshold for this Fermi transition is however 5.885 MeV [9]. In addition, the Gamow-Teller transitions were not included in the total absorption rate.

In this paper, we improve the estimates for supernova neutrino rates taking into

¹in ref. [9] a threshold $Q = 11.5$ is quoted in units of m_e .

account latest developments: we use new calculations in the random phase approximation (RPA) for the absorption processes[10] and consider all the processes that contribute to the total number of expected neutrino events, including for the first time the absorption reaction $\bar{\nu}_e {}^{40}\text{Ar}$. We discuss the ability to determine the direction of the supernova.

2 Supernova neutrino signatures

Models of type II supernovae predict that neutrinos are emitted with a thermal spectrum, with a temperature hierarchy among neutrino flavours: $T_{\nu_e} < T_{\bar{\nu}_e} < T_{\nu_\mu, \nu_\tau, \bar{\nu}_\mu, \bar{\nu}_\tau}$. The neutrino energy spectra can be described by a Fermi-Dirac distribution [11]:

$$\frac{dN}{dE_\nu} = \frac{C}{T^3} \frac{E_\nu^2}{1 + e^{(E_\nu/T - \eta)}} N_\nu \quad (1)$$

where $C = 0.55$; T is the temperature (MeV); E_ν the neutrino energy (MeV); η the chemical potential and N_ν the number of expected neutrinos of a given species. We use $\eta = 0$ [11]. The following values for the different neutrino temperatures are used, giving the following average energies:

$$\begin{array}{lll} \nu_e & T = 3.5 \text{ MeV} & \Rightarrow \langle E \rangle = 11 \text{ MeV} \\ \bar{\nu}_e & T = 5.0 \text{ MeV} & \Rightarrow \langle E \rangle = 16 \text{ MeV} \\ \nu_{\mu, \tau} & T = 8.0 \text{ MeV} & \Rightarrow \langle E \rangle = 25 \text{ MeV} \\ \bar{\nu}_{\mu, \tau} & T = 8.0 \text{ MeV} & \Rightarrow \langle E \rangle = 25 \text{ MeV} \end{array}$$

According to [12], pairs of neutrino flavours should be produced with equal luminosity. The total number of neutrinos of a given flavour is obtained dividing the binding energy by six (corresponding to all $\nu + \bar{\nu}$ species) and by the average energy associated to each species. As a result, ν_e 's will be more copiously produced than $\nu_{\mu, \tau}$'s since their mean energy is lower. Figure 1 shows the expected neutrino spectra for a binding energy of 3×10^{53} ergs. We expect 2.8×10^{57} ν_e , 1.9×10^{57} $\bar{\nu}_e$ and 5.0×10^{57} $\nu_{\mu, \tau} + \bar{\nu}_{\mu, \tau}$ for a total of 9.7×10^{57} neutrinos.

In argon two processes contribute to the total rate:

- **Elastic scattering:** $\nu_x + e^- \rightarrow \nu_x + e^-$ ($x = e, \mu, \tau$) sensitive to all neutrino species.
- **Absorption:** $\nu_e + {}^{40}\text{Ar} \rightarrow e^- + {}^{40}\text{K}^*$, $\bar{\nu}_e + {}^{40}\text{Ar} \rightarrow e^+ + {}^{40}\text{Cl}^*$

We consider two configurations of the detector with masses of 1.2 and 3 kton: the number of targets is accordingly:

	1.2 kton	3 kton
Elastic scattering	$3.2 \times 10^{32} e^-$	$8.0 \times 10^{32} e^-$
Absorption	$1.8 \times 10^{31} \text{ Ar nuclei}$	$4.5 \times 10^{31} \text{ Ar nuclei}$

2.1 Elastic events

The elastic neutrino scattering off electrons has a total cross section that increases linearly with energy:

$$\begin{aligned}
\sigma(\nu_e e^- \rightarrow \nu_e e^-) &= 9.20 \times 10^{-45} E_{\nu_e}(\text{MeV}) \text{ cm}^2 \\
\sigma(\bar{\nu}_e e^- \rightarrow \bar{\nu}_e e^-) &= 3.83 \times 10^{-45} E_{\bar{\nu}_e}(\text{MeV}) \text{ cm}^2 \\
\sigma(\nu_{\mu,\tau} e^- \rightarrow \nu_{\mu,\tau} e^-) &= 1.57 \times 10^{-45} E_{\nu_{\mu,\tau}}(\text{MeV}) \text{ cm}^2 \\
\sigma(\bar{\nu}_{\mu,\tau} e^- \rightarrow \bar{\nu}_{\mu,\tau} e^-) &= 1.29 \times 10^{-45} E_{\bar{\nu}_{\mu,\tau}}(\text{MeV}) \text{ cm}^2
\end{aligned} \tag{2}$$

All neutrino species contribute to elastic scattering. The experimental signature consists in a single recoil electron. Since, the direction of this electron is highly correlated to the incoming ν direction, these events have the potentiality of precisely determining the location of the supernova source.

Table 1 shows the expected rates for this reaction. To compute the number of events we fold the total cross section as a function of energy with the appropriate Fermi-Dirac distribution. Our rates are calculated integrating over all electron recoil energies. Since the neutrino burst occurs in a time window of about 10 seconds, we estimate that the background expected due to natural radioactivity is negligible and therefore we do not apply any threshold for electron detection.

Figure 2 shows the expected elastic event rates, as a function of the incoming neutrino energy, for the case of a 3 kton detector and a supernova occurring at 10 kpc. The largest contribution ($\sim 50\%$) to elastic events comes from ν_e , since they have both the larger flux and cross section. For a 3 (1.2) kton detector, we expect a total of 41 (16) elastic events.

Reaction	T (MeV)	$< E_\nu >$ (MeV)	Expected events	
			1.2 ktons	3 ktons
Elastic				
$\nu_e e^-$	3.5	11	8	20
$\bar{\nu}_e e^-$	5	16	3	8
$(\nu_\mu + \nu_\tau) e^-$	8	25	3	7
$(\bar{\nu}_\mu + \bar{\nu}_\tau) e^-$	8	25	2	6
total νe^-			16	41
Absorption				
$\nu_e {}^{40}\text{Ar}$	3.5	11	75	188
$\bar{\nu}_e {}^{40}\text{Ar}$	5	16	6	15
Total			97	244

Table 1: Expected neutrino rates for a supernova at a distance of 10 kpc, releasing an energy of 3×10^{53} ergs (no threshold on the electron energy has been applied).

2.1.1 Reconstruction of the incoming neutrino direction

It is possible to use the angular distribution of elastic scattering neutrino events to identify the direction of a nearby supernova. Ordinarily, this would be unnecessary due to the optical emissions. However, if one is interested in studying a galactic supernova's first hours or days or if the supernova is obscured in the optical by the dust of the galactic disk, the early warning and crude angular position provided by the neutrino data would be uniquely useful.

One method to achieve this is to use the fact that the electron produced via an elastic scattering is strongly forward-peaked and it will point back to the supernova direction. Depending on the type of the incident neutrino and its energy, one can expect the distributions of the secondary electrons to be confined to a certain effective scattering cone.

In order to estimate our angular efficiency, supernova neutrino events have been fully simulated using the FLUKA Monte Carlo package [13]. A detailed description of the ICARUS T600 geometry is included in the simulation [14]. The detector internal volume consisted of two half-modules filled with liquid argon. A fiducial volume of $3.2 \times 3.0 \times 18.0 \text{ m}^3$ has been considered for every half-module, surrounded by a dewar of stainless steel of 20 tons. An external container of aluminum and honeycomb acts as thermal insulator. Finally, a 70 cm thick layer of polyethylene tubes filled with boric acid has been simulated as a shield against neutrons.

Elastic events are characterized by the production of a primary electron track in the sensitive volume in a direction correlated with the incoming neutrino direction. The electron undergoes multiple scattering and Bremsstrahlung which leads to a deviation from the original direction, also affecting the angular reconstruction accuracy.

The signal deposited by the track in the detector is discretized in elementary *cells*, which correspond to the readout granularity of the detector. The detector volume is supposed to be divided in cells of $3 \times 3 \times 3 \text{ mm}^3$. Then, the energy associated to the track is computed from the charge deposited in every elementary cell.

The reconstruction of the electron momentum is performed by using the position of every cell with respect to the primary vertex weighted with the corresponding charge deposited in the cell. The algorithm can be optimized by varying the track length (and the consequent number of cells) considered in the reconstruction of the electron direction to avoid the multiple scattering effect.

Two different optimization methods have been tested in terms of two variables: the percentage of cells belonging to the electron track to be used in the reconstruction and the scattering angle of the electron.

In the first method we studied the variation of the angular resolution as a function of the percentage of cells taking into account in the momentum reconstruction. The angular resolution was computed as the RMS of the distribution $\theta^{rec}-\theta^{MC}$, the difference between the reconstructed and simulated angles between the electron and the

parent neutrino directions. Figure 4 shows this variation for different electron energy ranges. The percentage of cells used in the electron direction reconstruction giving the best angular resolution decreases when the electron energy increases.

The reconstructed and simulated angles for different electron energy ranges are plotted separately in figure 5. The value of the angle between the electron and the neutrino is dominated by the kinematics of the events and not by the reconstruction algorithm.

Figure 6 shows the expected angular resolution as a function of the electron energy for different percentage of cells. For low electron energies (< 2.5 MeV), almost all cells are needed to have an accurate reconstruction (90%). For energies between 2.5 and 16 MeV, the optimal resolution is obtained using the 50% of the cells and for electrons of more than 16 MeV only the 30% of the cells should be used.

Figure 7 shows the angular resolution obtained with the best reconstruction algorithm which uses the optimal percentage of cells for each electron energy range. The resolution decreases strongly at low energies, being below 16 degrees for events with electron energies of more than 5 MeV. For energies greater than 15 MeV the resolution is less than 8 degrees.

The second method is based on the dependence between the electron momentum and the scattering angle. The projected scattering angle can be obtained as [15]:

$$\langle \theta_i \rangle = \frac{13.6 \text{ MeV}}{\beta c p} \sqrt{\frac{x}{X_0}} \left[1 + 0.038 \ln \left(\frac{x}{X_0} \right) \right] \quad (3)$$

where x is the track length, p and βc are the momentum and velocity of the particle, and $X_0 = 14$ cm is the radiation length in LAr. Therefore the particle momentum, neglecting ionization losses, is proportional to the inverse of the average value of the scattering angles.

We select the track length for which the scattering angle is smaller than a certain threshold. This way, we reduce the effect of multiple scattering on the angular resolution.

Figure 8 shows the angular resolution as a function of the electron energy for different values of the scattering angle threshold. The same behaviour of the angular resolution as a function of the electron energy is observed with this method but slightly worse results are obtained. Events with electrons of more than 5 MeV have an angular resolution below 18 degrees. For more than 15 MeV, the resolution reached is essentially the same with both methods.

Therefore, the first algorithm based in the percentage of cells has been adopted for the reconstruction of the scattered lepton direction.

Figure 9 shows the fraction of events as a function of the cone angle within which the reconstructed electron direction in space is contained. The cone axis is defined by

the parent neutrino direction. The different curves correspond to different thresholds on the electron kinetic energy (T_{lep}). For a 25° cone around the neutrino direction and electron energies greater than 2 MeV, the angular efficiency is about 51%. It increases as a function of the threshold on the electron energy, being 66% for electrons of more than 5 MeV.

In order to determine the supernova explosion location, the angular distribution of the elastic scattering neutrino events was used. Figure 10 shows the distribution of the angle between the incoming neutrino and the outgoing electron for different electron energy thresholds. The uncertainty in the direction can be computed from the RMS of the distributions shown in figure 11. The sign of the angle refers to the projection of the electron momentum into an axis perpendicular to the neutrino direction. The contamination coming from absorption events reconstructed as elastic events is indicated in the plot. It is largely reduced as soon as we apply a cut on the lepton energy.

Therefore, the resulting uncertainty in the direction measurement of a supernova at a distance of 10 kpc is $\sim 70.6^\circ/\sqrt{N}$ for $T_{lep} > 0$ MeV, $\sim 38.9^\circ/\sqrt{N}$ for $T_{lep} > 2.5$ MeV and $\sim 28.8^\circ/\sqrt{N}$ for $T_{lep} > 5$ MeV, being N the expected number of elastic supernova events. The corresponding uncertainties obtained with a 1.2 kton and 3 kton detector are given in table 2, together with the expected elastic rates for different lepton energy thresholds.

T_{lep} (MeV)	Expected elastic events		Expected uncertainty	
	1.2 ktons	3 ktons	1.2 ktons	3 ktons
> 0	16	40	17.7°	11.2°
> 2.5	12	30	11.2°	7.1°
> 5	9	23	9.6°	6.0°

Table 2: Expected uncertainty in the direction measurement of a supernova at a distance of 10 kpc for a 1.2 kton and 3 kton detector for different electron energy thresholds.

2.2 Absorption events

The $\nu_e {}^{40}\text{Ar}$ absorption rate is expected to proceed through two main channels: a superallowed Fermi transition to the 4.38 MeV excited isobaric analog ${}^{40}\text{K}^*$ state; Gamow-Teller transitions to several excited ${}^{40}\text{K}$ states. These two processes can be distinguished by the energy and multiplicity of the γ rays emitted in the de-excitation and by the energy spectrum of the primary electron. In addition one can consider other processes which become important energies above 20 MeV, where the final state is not a bound state anymore and where emission of particles from the nucleus is possible.

The cross section for the Fermi ν_e capture is given by [9]:

$$\sigma = 1.702 \times 10^{-44} \frac{E_e}{m_e^2} \sqrt{E_e^2 - m_e^2} F(E_e) \text{ cm}^2 \quad (4)$$

where $F(E_e)$ is the Fermi function, $E_e = E_\nu - Q + m_e$ is the prompt electron energy, Q is the energy threshold ($Q = 5.885$ MeV) and m_e is the electron mass.

In reference [16] shell model calculations of ν_e absorption cross sections for ^{40}Ar are presented by Ormand *et al.* They show that GT transitions lead to a significant enhancement of the absorption rate over that expected from the Fermi transition.

In recent studies [10] the ν_e absorption cross section has been computed by random phase approximation (RPA) for neutrino energies up to 100 MeV. These calculations include all the multipoles up to $J=6$ and both parities, whereas only the 1^+ and 0^+ allowed transitions were considered in Ref. [16]. As shown in figure 3, both results are similar up to ~ 20 MeV. At higher energies relevant for supernova neutrinos, the cross section including all the multipoles increases faster, showing the importance of including higher multipoles in order to get a better estimate of the event rate.

The absorption cross section is much larger than that for ν_e elastic scattering, hence this process significantly enhances the experimental sensitivity (see table 1). In a 3 kton detector, we expect 188 ν_e absorption events from the supernova at 10 kpc.

The absorption process $\bar{\nu}_e + ^{40}\text{Ar} \rightarrow e^+ + ^{40}\text{Cl}^*$ is included for the first time, giving 15 events for a 3 kton detector. The corresponding cross section computed by RPA [10] is also plotted in figure 3. In this case the 1^+ and 0^+ allowed transitions are suppressed by nuclear structure reasons and the cross section is dominated by the other multipoles.

The total expected rate for a 3 kton (1.2 kton) detector is about 244 (97) events. This statistics would allow a detailed study of neutron star and even black hole formation and would largely contribute to get an improved knowledge of some neutrino intrinsic properties like, for example, the mass, electric charge and magnetic moment.

Figure 12 show the total rate for a 3 kton detector as a function of supernova distance. It also displays the expected rates for the different neutrino reactions. For a gravitational stellar collapse occurring in the Large Magellanic Cloud (distance ~ 60 kpc), we expect to collect, in a 3 kton detector, about 7 events as a result of the neutrino burst.

3 Conclusions

A liquid Argon TPC like ICARUS is sensitive to supernova neutrinos. A typical gravitational stellar collapse, occurring at 10 kpc, will produce a neutrino burst of about 97 (244) events in a 1.2 (3) kton detector. The largest contribution comes from the absorption process of ν_e neutrinos. Elastic scattering off electrons for all neutrino species

contributes to 15% of the total rate. The $\bar{\nu}_e$ absorption reaction has been studied for the first time, giving 15 events for a 3 kton detector.

The direction of the lepton momentum for elastic scattering neutrino events can be measured with good accuracy. A reconstruction algorithm has been optimized by varying the track length to be considered in the reconstruction. The contamination from absorption events in the elastic channel can be reduced cutting on the lepton energy. The expected angular resolution is below 16 degrees for lepton energies greater than 5 MeV. The resulting uncertainty in the direction measurement of a supernova at 10 kpc is 17.7° (11.2°) with a 1.2 (3) kton detector, reaching 9.6° (6.0°) for lepton energies greater than 5 MeV.

Neutrino oscillations will change significantly the expected number of events. Matter effects in the SN and vacuum oscillations will modify the neutrino fluxes. As a result of mixing, the original ν_e spectrum will be shifted to higher energies. This will increase dramatically the rate of ν_e ^{40}Ar absorption events due to the strong dependence of the cross section with the neutrino energy. Because of its sensitivity to ν_e neutrinos, a liquid Argon TPC can also provide unique information about the early breakout pulse that might be observed from the next galactic supernova. Analyses considering these features will be included in a following paper[17].

Acknowledgments

We would like to acknowledge G. Martinez-Pinedo, E. Kolbe and K. Langanke for their calculations on the neutrino cross sections in ICARUS and for very valuable discussions. We also thank A. Ferrari and P. Sala for their help on the FLUKA simulations.
